Supporting Information

ABSTRACT: Protein arrays are typically made by random absorption of proteins to the array surface, potentially limiting the amount of properly oriented and functional molecules. We report the development of a DNA encoded antibody microarray utilizing site-specific antibody—oligonucleotide conjugates that can be used for cell immobilization as well as the detection of genes and proteins. This technology allows for the facile generation of antibody microarrays while circumventing many of the drawbacks of conventionally produced antibody arrays. We demonstrate that this method can be used to capture and detect SK-BR-3 cells (Her2+ breast cancer cells) at concentrations as low as 10⁴ cells/mL (which is equivalent to 10⁵ cells per 100 μL array) without the use of microfluidics, which is 100- to 10⁵-fold more sensitive than comparable techniques. Additionally, the method was shown to be able to detect cells in a complex mixture, effectively immobilizing and specifically detecting Her2+ cells at a concentration of 10⁴ SK-BR-3 cells/mL in 4 × 10⁶ white blood cells/mL. Patients with a variety of cancers can have circulating tumor cell counts of between 1 and 10⁶ cells/mL in whole blood, well within the range of this technology.

INTRODUCTION

Protein microarrays have been used in many biomedical applications including the detection of proteins in serum, the analysis of protein—protein interactions, and the study of post-translational modifications.¹ Specifically, antibody-based proteomics can identify and validate cancer biomarkers as well as provide a diagnostic approach for identification of different tumor types.²,³ Recently, antibody microarrays have been used to identify metastatic breast cancer as well as distinguish patients with pancreatic cancer from healthy controls.⁴,⁵ Additionally, because antibody microarrays also have the ability to capture cells, they allow the possibility of detecting rare cells such as circulating tumor cells (CTCs).⁶,⁷

Although there are numerous applications for antibody arrays, construction of these protein arrays is a significantly greater challenge compared with conventional DNA microarrays. The generation of antibody microarrays requires immobilization of the antibody on either hydrophobic or chemically reactive (e.g., epoxy, aldehyde, maleimide) surfaces.⁸—¹⁰ However, this approach can cause denaturation and loss of activity due to immobilization of the protein in a nonproductive orientation or nonspecific binding of the protein to the surface. Approaches to preserve the protein conformation include three-dimensional matrices such as hydrogels and polyacrylamide, and light-directed biotin—avidin arrays.¹¹,¹² Alternatively, one can immobilize antibodies on a DNA array by first modifying the protein of interest with a single-stranded oligonucleotide.¹³,¹⁴ In general, this approach prevents protein denaturation and loss of binding activity associated with printing antibodies on a solid support and potentially allows for greater control of the orientation of the surface bound antibodies.¹⁵–¹⁷ Not only do these arrays allow for facile and rapid generation of antibody arrays, they have also been shown to have superior binding characteristics when compared to standard antibody arrays. Utilizing DNA directed antibody immobilization on a DNA microarray also allows for concomitant detection of multiple biomolecules, biomarkers, genes or cell types on a single platform.

The most common method for conjugating DNA to antibodies is by modification of surface exposed lysine residues. However, coupling to the lysine residues results in a heterogeneous mixture of products which can interrupt antigen binding and cause the antibodies to aggregate.¹⁸–²⁰ Random conjugation also prevents control of antibody orientation on the surface, which can lead to loss of activity and specificity. Peluso et al. reported up to a 10-fold increase in analyte binding capacity between a specifically oriented and a randomly oriented antibody using streptavidin-coated surfaces.¹¹ In the context of immuno-PCR, there was a significant difference in signal when comparing site-specific and random DNA
conjugation. Additionally, site-specific DNA–Fab conjugation has recently been used to develop an extremely sensitive homogeneous immunoassay, detecting PSA at concentrations of 0.27 ng/mL. The availability of genetically encoded unnatural amino acids with unique chemical reactivity can provide a solution to these challenges. Previously, we have site-specifically incorporated p-acetylphenylalanine (pAcF) and p-azidophenylalanine (pAzF) into proteins in response to amber nonsense codons in bacteria and mammalian cells. These amino acids have orthogonal chemical reactivity to the canonical 20 amino acids and can be conjugated efficiently and selectively to alkoxymine- or alkyne-derived reagents under mild conditions. Herein, we report the development of a DNA-directed antibody microarray technology utilizing site-specific antibody–oligonucleotide conjugates (Figure 1). This versatile platform can be used for cancer cell immobilization, as well as the detection of genes and proteins.

Figure 1. Synthesis of protein array using an anti-Her2 Fab with site-specific incorporation of pAcF. An excess of synthesized aminooxy-modified oligonucleotide (Scheme S1) is added to anti-Her2 pAcF Fab and incubated at 37 °C for 16 h. After purification, the anti-Her2-oligonucleotide conjugate is added to the array and annealed to its complementary strand. Her2 positive tumor cells can then be captured and analyzed.

**RESULTS AND DISCUSSION**

As an initial proof-of-concept, we used this platform for the detection of Her2+ cancer cells. To produce a model DNA-directed antibody microarray, we used trastuzumab (Herceptin), an approved monoclonal antibody for the treatment of Her2 overexpressing breast cancers. An anti-Her2 pAcF Fab was expressed using an orthogonal amber suppressor aminoacyl-tRNA synthetase/tRNA pair specific for pAcF. The previously reported pBAD/pEVOL expression system was used to substitute pAcF at surface-exposed site S202 in the light chain. This site was chosen due to its previously reported high efficiency. In addition, modification at this site does not affect antigen binding affinity or specificity. Anti-Her2 S202pAcF mutant Fab was expressed in E. coli in good yields (>2 mg/L shake flasks, >400 mg/L fermentation), purified by Protein G, and characterized by SDS-PAGE gel and electrospray-ionization mass spectrometry (ESI-MS) (Expected 47 860 Da; Observed 47 861 Da). As depicted in Figure 2A, lane 2, only one band is observed after Protein G purification, indicating >95% purity. The antibody–oligonucleotide conjugates were then produced via the protocol outlined in Kazane et al., utilizing an aminooxy-functionalized single-stranded oligonucleotide to achieve bio-orthogonal condensation with the ketone moiety and form a stable oxime linkage. Anti-Her2 S202pAcF Fab was conjugated to aminooxy-modified oligonucleotide sequences (C′ and D′, Table S1) (100 μM Fab, 3 mM oligonucleotide, 100 mM methoxy aniline, pH 4.5, 37 °C, 16 h), purified by anion exchange chromatography (Mono Q 5/50 GL), and analyzed by SDS-PAGE (Figure 2A and S1). As depicted in Figure 2A, there is only one band (lanes 3 and 4) which correspond to the homogeneous site-specific Fab-oligonucleotide conjugate.

Immobilization experiments with anti-Her2–oligonucleotide conjugates were performed on slides containing six 5 × 5 subarrays (Figure 2B, left) with each sub array comprising different DNA sequences (DNA sequences A–F, Table S1). Thus, the subarray C would be expected to hybridize to its complementary oligonucleotide C′, for example. These arrays were printed onto NHS-ester coated glass slides, which were blocked for 1 h with 50 mM ethanolamine in 0.01% PBST. The antibody conjugate was added onto the DNA arrays via the direct addition of 100 μL of 2 μM (100 μg/mL) anti-Her2 Fab–oligonucleotide conjugate and hybridized for 15 min at room temperature (rt). SYBR green (which has a much higher sensitivity for dsDNA than for ssDNA) was used to verify that
the DNA on the array had hybridized to its complement and therefore bound the Fab–oligonucleotide conjugate (data not shown). Additionally, anti-κ R-Phycocerythrin (R-PE) was used to confirm the presence of the antibody at the desired positions, and to show this method’s ability to localize and image labeled proteins. As shown in Figure 2B, anti-Her2 S202pAcF-C’ (middle) and anti-Her2 S202pAcF-D’ (right) both hybridized to the correct subarray with minimal nonspecific binding to the other subarrays (Figure S2).

Next, we analyzed the binding and capture of Her2 positive tumor cell lines. For the cell immobilization experiments, an evanescent field (EF) reader was utilized to image wet slides containing the immobilized live cells. Experiments were performed on slides containing 8 × 8 subarrays of DNA sequences C and D. The initial conditions used were as follows: hybridization of 10 μg (100 μL of a 100 μg/mL (2 μM) solution) of the antibody conjugate (15 min rt), followed by the addition of 10^6 cells/mL of SK-BR-3 (Her2+) or MDA-MB-231 (Her2−) cells (30 min rt). The cells were stained with CellTracker Orange (Life Technologies) so that live cells could be imaged using a 555 nm excitation. Her2 positive cells (SK-BR-3) bound to the protein array, with >1000-fold difference in signal compared to Her2 negative cells (MDA-MB-231) (Figure 2C and Figure S3). To ensure that the cells were selectively bound to the array, we performed the experiment in the absence of the antibody at the desired concentration of cells. Anti-Her2 S202pAcF-C′ hybridized to the correct subarray with minimal nonspecific binding, and to show this method’s ability to localize and image labeled proteins. As shown in Figure 2B, anti-Her2 S202pAcF-C’ (middle) and anti-Her2 S202pAcF-D’ (right) both hybridized to the correct subarray with minimal nonspecific binding to the other subarrays (Figure S2).

Next, we tested the sensitivity of this method via a titration of the concentration of cells. Anti-Her2 S202pAcF-C’ was hybridized to the array and different concentrations of SK-BR-3 cells (2 × 10^4 to 1 × 10^7 cells/mL) were added to each well of the slide (100 μL/array) and an evanescent field reader was used to image the slides at 555 nm excitation. Signal can be easily detected at the lowest concentration (∼1000 cells/array), whereas comparable methods (Herceptin localized via printed anti-human Fc antibody, and Herceptin directly printed on the array) had significantly worse detection limits (Figure S6). For further confirmation, we imaged the cells with both an evanescent field reader and bright field microscopy to confirm the presence of cells on the array (Figure S7). We then investigated if precomplexing the antibody conjugate with the cells would impact the array binding. A series of dilutions of the antibody conjugate were prepared and combined with aliquots of SK-BR-3 cells (10^5 cells/mL) before being added to the DNA array (Figure 3). Using the previously described conditions (10 μg Fab-oligonucleotide and 10^6 cells/mL), almost no binding was observed. This is most likely due to excess antibody–oligonucleotide conjugate hybridizing to the array and competing with the cell/antibody complex. However, we found that precomplexing the antibody conjugate with the cells allows for the use of orders of magnitude less antibody, with a visible signal all the way down to 20 pM (100 pg/well) of antibody conjugate (with a maximum signal at 2 nM (10 ng/well) of conjugate).

In order to use this application as a diagnostic tool, the DNA-encoded antibody microarray must be able to bind specific cells in a complex mixture. In this regard, we performed a mixing experiment with white blood cells and tumor cells. Red blood cells (RBCs) from a healthy donor were lysed (150 mM NH₄Cl, 10 mM KHCO₃, 130 mM EDTA), pelleted, and the RBCs in the supernatant were aspirated. The remaining white blood cells (WBCs) were resuspended in PBS (pH 7.4). Varying concentrations of SK-BR-3 cells (stained with CellTracker Orange) were spiked into 4 × 10^6 WBCs/mL. One microgram of anti-Her2 S202pAcF-C’ conjugate was hybridized to the slide and the spiked sample was added followed by the addition of an anti-Her2-AlexaFluor 488 conjugate (made through site-specific conjugation with anti-Her2 S202pAcF Fab and aminooxy-Alexa Fluor 488 from Life Technologies). The inclusion of the additional anti-Her2–Alexa Fluor 488 conjugate allows for imaging on both the 555 and 488 nm excitation channels and enables confirmation that the SK-BR-3 cells are bound to the array. As depicted in Figure 4, 10^5 SK-BR-3 cells/mL spiked into 4 × 10^6 WBCs/mL bound to anti-Her2 S202pAcF-C’ with excellent selectivity (compared to the negative control of only 4 × 10^6 WBCs/mL). Additionally, cells were detected down to a concentration of

![Figure 3](image-url)
for the detection of CTCs. Additionally, because these arrays are printed on coated microscope slides, any immobilized cells could undergo immunohistochemistry (IHC) or immunofluorescence (IF) for detection and analysis of other CTC markers.

**CONCLUSION**

In summary, by utilizing the site-specific incorporation of the pAcF unnatural amino acid into a Fab, we developed a DNA directed antibody microarray system that allows for the facile generation of antibody microarrays while circumventing many of the drawbacks of conventionally produced antibody arrays (e.g., denaturation of the antibody during production, and poor shelf life). Additionally, because this microarray is generated on a DNA array platform, it allows for concomitant analysis of genes, proteins, and/or cell types. This microarray has been shown to immobilize cells at cell concentrations significantly lower than that of comparable methods, making it potentially useful as a method for detecting circulating tumor cells.
